Intrinsically disordered protein domains exist in more than a third of eukaryotic proteins where they mediate diverse context dependent molecular associations ranging from RNA management to protein aggregation events in at least 40 amyloid protein diseases. The oligomer cascade hypothesis holds that metastable aggregates of amyloid- β (A β) initiate and propagate neurodegeneration in Alzheimer's disease as a protein-only infection. We will discuss how these liquid-liquid phases carry dynamic kinetic information that can be used to control mesoscale molecular order via substrate-level inception of the ultimate liquid-solid transition.
